

New insights into what drives organ transplant rejection

6 September 2018

When it comes to transplant rejection, some organs are far trickier than others. Some transplantable organs, such as the liver, are readily accepted by the recipient's immune system, rarely triggering an immune response and rejection. But the skin is a very different matter: Skin grafts have a high rate of rejection for unknown reasons.

Investigators from Brigham and Women's Hospital set out to understand why, hoping to capitalize on new biological insights to not only explain why [skin](#) transplants provoke the immune system but also what treatments can be given to an organ prior to transplantation to decrease the likelihood of [rejection](#). Their findings, with implications for the future of face transplantation, are published in *Nature Communications*.

"Our work in the lab is driven by clinical observation," said co-senior author Leonardo V. Riella, MD, Ph.D., medical director of the Vascularized Composite Tissue Transplant Program at BWH. "Skin grafts have such a high rate of rejection compared to other organs. We wanted to find out why."

Using a mouse model of skin transplantation, the team identified a novel, specific subset of cells in donor transplanted organs that triggered rejection. Known as CD103+ dendritic cells, this cell type appeared to play a major role in rejection. In its absence, researchers observed fewer signs that the recipient's immune system had been triggered and found that the transplanted skin survived longer.

In addition, the team was able to mitigate rejection by treating organs prior to transplantation. When [skin grafts](#) were incubated with an anti-inflammatory mycobacterial protein, the grafts survived longer after transplantation. This effect was mediated by March-1, an enzyme that can inhibit the maturation of CD103+ dendritic cells in donor grafts. In addition to these observations in mouse models, the team also tested the effect of adding the mycobacterial protein to human skin grafts, finding signs that this treatment may help prevent an immune reaction.

Pre-treating skin grafts or other organs prior to transplantation represents a new, complementary strategy for preventing [organ rejection](#). "Today, most treatment focuses on the recipient side, using immunosuppressive drugs to try to prevent rejection," said Riella. "What we propose is a complementary strategy to tame the rejection process through direct treatment of the donor organ prior to transplantation. This could offer many benefits since we're focusing on an arm of the immune system—innate immunity—that immune suppressors cannot regulate."

The researchers plan to continue testing safety and effectiveness of this strategy in preclinical models and, if successful, will conduct phase 1 clinical trial in humans in the years ahead.
